Time-series modeling of epidemics in complex populations:

detecting changes in incidence volatility over time

Trends in infectious disease incidence provide important information about epidemic dynamics and prospects for control. Higher-frequency variation around incidence trends can shed light on the processes driving epidemics in complex populations, as transmission heterogeneity, shifting landscapes of susceptibility, and fluctuations in reporting can impact the volatility of observed case counts. However, measures of temporal volatility in incidence, and how volatility changes over time, are often overlooked in population-level analyses of incidence data, which typically focus on moving averages. Here we present a statistical framework to quantify temporal changes in incidence dispersion and detect rapid shifts in the dispersion parameter, which may signal new epidemic phases. We apply the method to COVID-19 incidence data in 144 United States (US) counties from the January 1st, 2020 to March 23rd, 2023. Theory predicts that dispersion should be inversely proportional to incidence, however our method reveals pronounced temporal trends in dispersion that are not explained by incidence alone, but which are replicated across counties. In particular, dispersion increased around the major surge in cases in 2022, and highly overdispersed patterns became more frequent later in the time series. These findings suggest that heterogeneity in transmission, susceptibility, and reporting could play important roles in driving large surges and extending epidemic duration. The dispersion of incidence time series can contain structured information which enhances predictive understanding of the underlying drivers of transmission, with potential applications as leading indicators for public health response.

28 Author summary

Understanding patterns in infectious disease incidence is crucial for understanding epidemic dynam-29 ics and for developing effective public health policy. Traditional metrics used to quantify incidence 30 patterns often overlook variability as an important characteristic of incidence time series. Quanti-31 fying variability around incidence trends can elucidate important underlying processes, including 32 transmission heterogeneity. We developed a statistical framework to quantify temporal changes 33 in case count dispersion within a single time series and applied the method to COVID-19 case count data. We found that conspicuous shifts in dispersion occurred across counties concurrently, 35 and that these shifts were not explained by incidence alone. Dispersion increased around peaks in 36 incidence such as the major surge in cases in 2022, and dispersion also increased as the pandemic 37 progressed. These increases potentially indicate transmission heterogeneity, changes in the susceptibility landscape, or that there were changes in reporting. Shifts in dispersion can also indicate 39 shifts in epidemic phase, so our method provides a way for public health officials to anticipate and manage changes in epidemic regime and the drivers of transmission.

42 Introduction

Time series of infectious disease incidence appear, to varying degrees, "noisy", showing higher frequency fluctuations (e.g., day-to-day or week-to-week fluctuations) around trends at the broader temporal ranges typical for epidemic curves (e.g., months or years). Short-term fluctuations in incidence time series are caused in part by variable reporting, but may also reflect the population-level impacts of transmission heterogeneity and changes in the landscape of susceptibility [1, 2, 3, 4, 5, 6, 7, 8]. Metrics of variability in incidence time series may therefore carry information regarding underlying drivers of transmission, and offer a relatively unexplored avenue for understanding epidemic dynamics.

Contact tracing data has revealed temporal changes in the variability of individual reproductive 51 numbers, quantified by shifts in the dispersion parameter of the offspring distribution in branching process models [7, 8]. Similar evidence has been recovered through statistical reconstruction of 53 transmission networks, indicating temporal trends in the level of dispersion at different phases of an epidemic [3]. However, the scaling from individual-level transmission heterogeneity to populationlevel epidemic dynamics is not fully understood. In addition, traditional contact tracing is very resource intensive, and although new approaches using digital technologies may improve its speed 57 and scalability [9], it would be helpful to have complementary population-level analyses that can estimate heterogeneity using incidence data, which is more widely available. The importance of considering population-level variability and its relationship to individual-level variability is further 60 highlighted by the finding that a combination of individual-based and population-based strategies were required for SARS-CoV-2 control during the early phases of the pandemic in China [6]. An important challenge therefore is to develop methods that can detect changes in population-level 63 variability in incidence time series, and to interpret these changes in terms of underlying transmission processes.

Emerging statistical techniques are leveraging variability in epidemic time series to enhance understanding of disease dynamics at the population level. For example, a recently-developed method uses population-level incidence data to estimate the dispersion parameter of the offspring distribution, which quantifies heterogeneity in secondary cases generated by an infected individual [5]. It is also possible to estimate the dispersion parameter of the offspring distribution from the distribution of the final size of a series of localized outbreaks [10]. Clustering of cases has also been estimated directly from incidence data [11]. Another important application links variability in inci-

dence to epidemic phases; for example, changes in the mean and interannual coefficient of variation
of measles incidence have been used to identify a country's position on the path to elimination,
providing insights into vaccination strategies and epidemiological dynamics [12]. Analysis of the
shape of epidemic curves for influenza in cities may identify contexts where incidence is focused
more intensely (proportionally more infections in a smaller span of time) with implications for the
sensitivity of cities to climate forcing and for surge capacity in the health system [4, 13].

What drives incidence dispersion and how does it relate to the underlying branching process of 79 transmission, and to observations of cases? Under a wide range of configurations for a branching 80 process model of contagion spread, the number of infected individuals I_t at time t will have a 81 negative binomial distribution [14, 15], $I_t \sim NB(\mu_t, \theta_t)$, where μ_t is the expectation for I_t and θ_t is the dispersion parameter. The variance is related to the mean and dispersion parameters by $Var[I_t] = \mu_t + \mu_t^2/\theta_t$, so smaller values of the dispersion parameter θ_t correspond to increasing amounts of dispersion, which increase the amounts by which the variance in realized number infected I_t exceeds the expected value, μ_t . Conversely, the distribution of I_t tends to a Poisson distribution (where the variance equals mean) as θ_t becomes large. The negative binomial distribution may also 87 accurately model a time series if there is a changing process mean within a time step: for example, if the mean of a Poisson distribution itself follows a gamma distribution, the resulting distribution is negative binomial. Negative binomial regression (in contrast to Poisson regression) can account for unobserved heterogeneity, time dependence in the rate of a process and contagion within a time 91 step that all lead to overdispersion [16].

An interpretation of the dispersion parameter for a time series model of counts is that events are $1 + \theta^{-1}$ times as "crowded" in time relative to a Poisson process with the same mean [17] (see derivation in S1 Text). For example, $\theta = 1$ corresponds to a situation where the average number of infections in the same time step as a randomly selected case will exceed the Poisson expectation by a factor of two. In a simple example relevant to surge capacity in healthcare systems, $\theta = 1$ implies that a random infectious individual visiting the emergency department at a hospital would find it on average to be twice as crowded with other infectious individuals (infected by the same pathogen) as expected for a Poisson process with the same incidence rate.

In a sufficiently large host population, and when the infectious pathogen can be assumed to spread in nonoverlapping generations, the number of infections each generation is often modeled as

$$I_{t+1} \sim NB(\mu_t = R_t I_t, \theta_t = I_t) \tag{1}$$

where time-varying reproductive number R_t gives the expected number of secondary infections 103 acquired from an infected individual at time t, and the generation time is set to 1 without loss of 104 generality [14, 18]. Setting $\theta_t = I_t$ arises from the assumption that individuals who acquire the 105 infection at time t form independent lineages with identically distributed local rate parameters. In 106 applications, this model for theta becomes $\theta_t = C_t/\rho_t$ where C_t represents reported cases and ρ the 107 reporting rate, which relates reported cases to the true number of infections as $C_t = \rho_t I_t$. However, 108 this requires that susceptible depletion in one lineage does not affect another, that transmission 109 rates are equal across lineages, and that reporting rates do not vary across lineages. 110

In practice, these assumption will not often hold, and our aim in this paper is to develop, test and apply an alternative approach which produces data-driven estimates of θ_t , including identifying timepoints when θ is changing rapidly, which may help to reveal the impacts of heterogeneity in transmission, susceptibility, and reporting.

116 By definition incidence volatility is fast relative to broadscale epidemic dynamics.

Consequently, in order to estimate incidence volatility we first modeled incidence at broad spatiotemporal scales using natural splines [19]. To allow for diverse shapes in the broadscale epidemic dynamics, spline modeling was conducted within a moving window such that for each half of the window

$$\log\left(\frac{\mu_t}{N}\right) = \sum_{j=1}^{J} \beta_j^{(t)} h_j(t) \tag{2}$$

where N represents population size, $h_j(t)$ are basis functions, the degrees of freedom is equal to the number of knots k for the natural spline, J = k + d + 1, where d is the degree of the polynomial, and $\beta_j^{(t)}$ are fitted parameters. The window has half-width Δ , centered at t, i.e., extending from $t - \Delta$ to $t + \Delta$. The degrees of freedom (number of knots) to be used for the splines, and the width of the moving window will depend on the application. Explanation of the specific choices we used for our application to COVID-19 cases in US counties is described below.

Modeling the underlying epidemic dynamics based on log-transformed incidence allows us to address the statistical effects of population size on the relationship between the mean and variance in count data, which would otherwise confound our analysis. Specifically, since population size influences the mean and variance of case count data, it impacts dispersion in different-sized populations that are otherwise identical. Accordingly, population size appears as an offset in our

model of broad-scale incidence changes. That is,

$$\log(\mu_t) = \sum_{j=1}^{J} \beta_j^{(t)} h_j(t) + \log(N)$$
(3)

The form of the probability mass function (PMF) for infections at a time step is:

$$f_t(I) = \binom{I+\theta-1}{I} \left(\frac{\mu}{\mu+\theta}\right)^I \left(\frac{\theta}{\mu+\theta}\right)^{\theta} \tag{4}$$

where μ is estimated via the linear predictor outlined above.

We estimate θ_t from observed incidence data using an iteratively reweighted least-squares (IRLS) 135 procedure for mean estimation, combined with the optimize function in R, which uses a combination 136 of golden section search and successive parabolic interpolation, to compute θ_t . Specifically, within each time window, the spline model with an offset term was used to estimate a series of μ_s values 138 for $s=t-\Delta$ to $s=t+\Delta$ via IRLS, as implemented in the NBPSeq R package [20]. A single value 139 of θ_t was then calculated for the entire time window by maximizing the likelihood function, which is based on the negative binomial probability mass function defined above.

In addition to fitting the model at each time step, we developed a likelihood-ratio test (LRT) to test the hypothesis that θ has changed at each time step. This test involves fitting and comparing two models: a null model (no θ change) and a two-part model (with a θ change). For the null model, a single θ value was fitted for the entire time window. For the θ -change model, separate θ values were fitted for the left (from $t-\Delta$ to t) and right (from t to $t+\Delta$) halves of the time window.

Very large θ values correspond to processes that are operationally identical to a Poisson process. Accordingly, the test does not produce a p-value if any of the three θ estimates exceed a user-specified threshold. In the application below, we set this threshold at 10^3 , meaning that θ estimates with temporal crowding within 0.1% of that expected for a Poisson process were considered effectively Poisson.

Similarly, values of θ very close to 0 focus all of the mass of the PMF on 0, representing a scenario where the probability of observing any infections approaches zero. As with the Poissonlike tolerance described in the previous paragraph, our algorithm does not produce a p-value if any of the three θ estimates are below a user-specified threshold. This threshold will depend on the presence of contiguous sections of the time series being analyzed during which no cases are observed. In the application below, we set this threshold to 10^{-3} , because θ values below this level correspond to 0 frequencies that greatly exceed those in the data.

With both upper and lower θ thresholds—corresponding to Poisson-like and zero tolerances, 160 respectively—maximum likelihood estimates (MLEs) of θ beyond these thresholds exhibited un-161 bounded behavior. When θ exceeded the upper threshold, corresponding to processes operationally 162 identical to a Poisson process, the MLE tended to grow arbitrarily large, with the likelihood func-163 tion reaching its maximum at the upper boundary of the calculated domain. Conversely, when θ fell 164 below the lower threshold, representing extreme overdispersion with probability mass concentrated 165 near zero, the MLE approached zero, and the likelihood function peaked at the lower boundary of 166 the domain. This behavior reflects the inability of the model to reliably estimate θ when it lies 167 outside the specified thresholds (Fig 1). 168

169 Application to simulated data

We evaluated the robustness of our framework to a range of population sizes, magnitudes of dis-170 persion changes, and shapes of underlying incidence trends by generating 2,000 simulated epidemic 171 curves with known parameters. Epidemic trends were modeled as smoothed incidence series derived 172 from 16-week sections randomly selected from US COVID-19 data (described below), scaled to re-173 flect different population sizes ranging from 10^3 to 10^7 . For each simulated trajectory, dispersion 174 parameters (θ_1 and θ_2) were assigned to the two halves of the selected 16-week window, and case 175 counts were simulated using a negative binomial distribution, where the mean (μ) was based on 176 the smoothed incidence trend scaled by the population size. The values of θ_1 and θ_2 were drawn 177 from a uniform distribution spanning 10^{-2} to 10^2 , with 10% of simulations set to have no change in 178 dispersion ($\theta_1 = \theta_2$). Extremely large differences in dispersion (absolute log-ratio > 3) were capped by setting $\theta_2 = \theta_1$. 180

181 Application to empirical data

We applied our framework to COVID-19 case data for the United States at the administrative level of counties, compiled by The New York Times, based on reports from state and local health agencies between Jan 4, 2020, and March 18, 2023 [21], and using county population sizes estimated for 2021 from the United States Census Bureau [22]. Cumulative cases for the largest three counties in each state were converted to weekly counts by keeping the last observation from each week and differencing to compute new cases. Occasionally, reported cumulative case counts were not

monotonically increasing due to corrections posted by local agencies as they resolved incoming data. 188 As a result, approximately 0.24% of estimated new cases across all counties in the dataset were 189 negative and these were set to zero. For each county, we analyzed overlapping 16-week windows, 190 shifting one week (i.e., one timestep) at a time. Within each window, the framework estimated 191 the dispersion parameter (θ) using a natural spline with three degrees of freedom for each half of 192 the window to model the broad-scale trend in incidence. Outputs included estimated dispersion 193 parameters (θ_1 , θ_2 , for the left and right halves of each window, and θ for the entire window), 194 likelihood ratio test statistics, p-values for changes in dispersion at the midpoint of the window, 195 and flags for boundary conditions such as failure to reject Poisson-like dispersion or collapse to 196 extreme overdispersion.

198 Results and Discussion

Simulations indicate that the LRT framework accurately detects changes in dispersion, with p-values 199 converging to 0.5 as the effect size approaches 0, reflecting the uniform distribution of p-values under 200 the null hypothesis, and decreasing toward zero as the effect size increases (Fig 1). The framework 201 is also robust to the range of population sizes present in the empirical data—county populations 202 ranged from approximately 48 thousand to 9.9 million, and we tested the framework on simulated 203 populations between 10 thousand and 10 million. Across this range, the method produced accurate 204 estimates for θ within $10^{-2} \le \theta \le 10^2$, encompassing all operationally relevant values for COVID-19 205 incidence data and many other infectious diseases. Lower values would concentrate the probability 206 mass function (PMF) for cases almost entirely on 0, while higher values effectively correspond to a 207 Poisson distribution. 208

Detecting dispersion changes in case count time series. a: Weekly incidence of COVID-19 in the United States, with time measured in weeks since January 4, 2020, showing an example of a randomly-selected 16 week period used as an incidence trend when in simulation-based validation of the LRT test (red). b: Cases in one county (Douglas County, Nebraska) over the sample time period with estimated incidence trend (red) and estimated dispersion values on either side of the midpoint. c: Estimated θ versus true θ in simulation studies combining a randomly-selected section of the national incidence curve with a random population size and set of dispersion values. Estimated values outside of tolerance plotted in purple (close to Poisson) and blue (close to collapsing to zero). d: Statistical power of the LRT test.

Applying the method to COVID-19 cases in US counties enabled investigation of changes in 209 dispersion in relation to both observed trends and model expectations based on case counts (Fig 2). 210 Periods of increased case count variability corresponded with decreases in θ , indicating that dis-211 persion was dynamic. Changes in dispersion exhibited both expected and unexpected patterns of 212 variation relative to standard theory. In some instances, θ varied inversely with incidence, consistent 213 with standard epidemic theory, while in other periods, deviations from this expectation occurred, 214 potentially signaling shifts in underlying transmission dynamics. Notably, significant changes in the 215 dispersion parameter were observed during major epidemic transitions. For example, during the 216 beginning of 2022, and at the end of the time series, when the pandemic was transitioning toward 217 endemicity as the landscape of susceptibility was evolving [23]. The landscape of susceptibility 218 was evolving as a larger proportion of cases involved reinfections. These findings underscore the 219 complex behavior of the dispersion parameter, which not only varied with changes in case count 220 regimes but also revealed departures from the model expectations described by Eq (1), which are 221 consistent with changes in the underlying drivers of transmission. 222

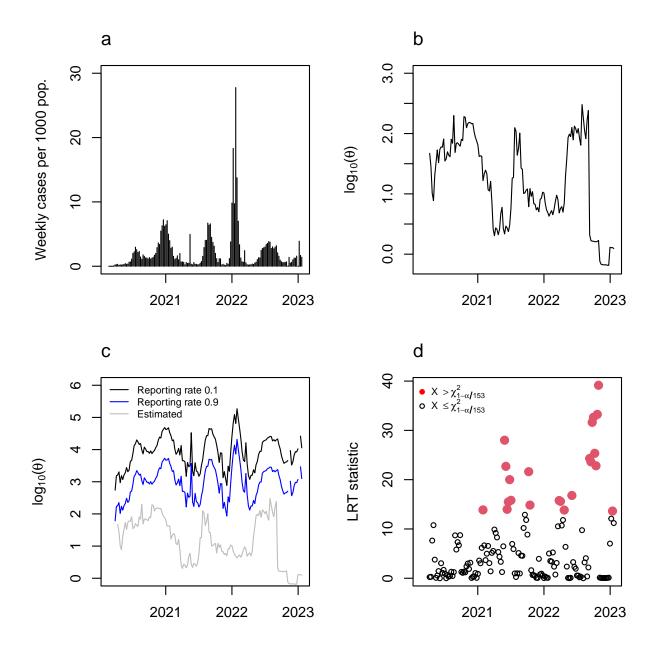

Fig 2. Dispersion analysis of weekly COVID-19 case data for Jefferson County, Alabama. Results for all counties are shown in Figure 3 a: Weekly reported COVID-19 incidence. b: Estimated dispersion parameter (θ) over time. c: Comparison of estimated dispersion (gray) with predicted values from the standard model $\theta_{t+1} = C_t/\rho_t$, where C_t is reported cases and ρ_t is the reporting rate. Predictions are shown for fixed $\rho_t = 0.1$ (black) and $\rho_t = 0.9$ (blue), chosen to encompass the range of θ expected under variable ρ . d: Likelihood ratio test (LRT) statistic over time. Statistically significant changes in dispersion (red) correspond to p-values below the Bonferroni-corrected 5% threshold of a chi-square distribution with one degree of freedom.

Dispersion increased markedly around the peaks in incidence during the major 2022 wave, from 223 late December 2021 to early February 2022 (Fig 3). This is in strong contrast to standard epidemic 224 theory which predicts that dispersion should decrease as incidence rises. A high concentration of 225 low p-values around peak incidence (Fig 3) corroborates widespread changes in θ across counties, 226 reinforcing the statistical significance of this pattern. While these p-values should be corrected for 227 multiple testing if used for inference rather than visualization, the overall trend suggests a sys-228 tematic departure from theoretical expectations. Highly overdispersed patterns were also observed 229 more frequently later in the time series, pointing to increasing heterogeneity in transmission, sus-230 ceptibility, and reporting during the later phases of the pandemic. In both the 2022 wave and 231 later in the pandemic, localized surges indicated by higher dispersion may have played a larger role in pandemic dynamics than expected, including potentially placing increased demand for surge 233 capacity in hospitals and testing centers. 234

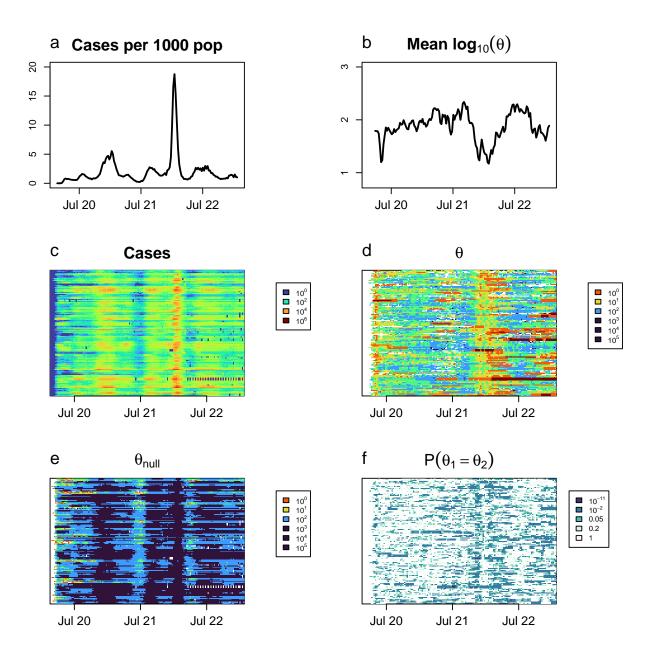

Fig 3. Incidence and dispersion between Jan 4, 2020 and March 18, 2023, in large counties in the US. a: Mean COVID-19 cases of the 144 US counties over time. b: Mean $\log_{10} \theta$ of the 144 US counties over time. c: $\log_{10}(cases)$ over time for each of the 144 counties. d: $\log_{10} \theta$ over time for each of the 144 counties. e: Expected value of $\log_{10} \theta_0$ under the null model, assuming a reporting rate of 0.5. f: LRT p-values over time for each location.

Our method forms part of a larger interest in investigating variability in infections as an impor-235 tant attribute of epidemic time series using novel metrics. For instance, burst-tree decomposition 236 of time series has also facilitated computation of a burst-size distribution for a series given a spec-237 ified time window [24], allowing comparison of variability within one location over time. Spatial 238 variation in superspreading potential has been investigated through risk maps of superspreading 239 environments [25], and future work could investigate the correspondence between dispersion in 240 case count time series, as quantified here, and indicators of a high risk of superspreading, with 241 the potential to further elucidate drivers of transmission risk across scales, and more finely resolve 242 landscapes of susceptibility. Additionally, as population-wide disease control may be less effective 243 than those which are focused to individuals in high-transmission contexts [1], identifying candidate time periods when transmission heterogeneity is high may catalyze the development of more ef-245 fective control strategies, particularly those that connect vulnerable populations with resources at 246 critical times. The finding that dispersion increased rather than decreased during the 2022 surge challenges theoretical expectations and suggests that fundamental assumptions about the scaling of 248 transmission dynamics may require reevaluation. One hypothesis is that transmission heterogeneity 249 could play a role in driving large surges, amplifying incidence beyond what homogeneous models predict. Future work could investigate whether bursts of highly clustered transmission events gen-251 erate feedback that accelerates epidemic spread, which, if true, could refine predictive models of 252 contagion dynamics in complex populations. 253
